Abstract

Given a term rewriting system R and a normalizable term t , a redex is *needed* if in any reduction sequence of t to a normal form, this redex will be contracted. Roughly, R is *sequential* if there is an optimal reduction strategy in which only needed redexes are contracted. More generally, G. Huet and J.-J. Lévy define in [8] the sequentiality of a predicate P on partially evaluated terms. We show here that the sequentiality of P is definable in SkS, the second-order monadic logic with k successors, provided P is definable in SkS. We derive several known and new consequences of this remark: 1- *strong sequentiality*, as defined in [8], of a left linear (possibly overlapping) rewrite system is decidable, 2- *NV-sequentiality*, as defined in [15] is decidable, even in the case of overlapping rewrite systems 3- *sequentiality* of any linear shallow rewrite system is decidable.

Then we describe a direct construction of a tree automaton recognizing the set of terms that do have needed redexes, which, again, yields immediate consequences: 1- Strong sequentiality of possibly overlapping linear rewrite systems is decidable in EXPTIME, 2- For strongly sequential rewrite systems, needed redexes can be read directly on the automaton.

1 Introduction

Besides confluence, there are two important issues concerning non-terminating computations in term rewriting theory. One is to find a *normalizing reduction strategy*, which has been investigated in, e.g., [14, 10, 1]. The other is to find an *optimal reduction strategy*, for which only *needed redexes* are contracted. This question was first investigated by Huet and Lévy in 1978 [8]. They call *sequential* a rewrite system for which there exists such an optimal strategy. We focus here on the latter issue.

A typical example is the “parallel or”, whose definition contains the two rules $\top \vee x \rightarrow \top$ and $x \vee \top \rightarrow \top$. Given an expression $e_1 \vee e_2$, which of e_1 and e_2 should be evaluated first? If e_1 is tried first, its evaluation may be unnecessary because e_2 evaluates to \top , and the whole expression can be reduced to \top . Hence, this strategy is not optimal. Evaluating e_2 first is not optimal either: there is no optimal (sequential) reduction strategy for the “parallel or”.

Given a term rewriting system R , can we decide whether R is *sequential*? In case it is, is it possible to compute (and compile) an optimal strategy? These questions have been addressed in several papers, starting with [8]. Unfortunately, the sequentiality of R is in general undecidable. In their landmark paper, Huet and Lévy introduce a sufficient criterion: *strong sequentiality*, and show that this property is decidable for *orthogonal term rewriting systems*, in which left hand sides do not overlap nor contain repeated occurrences of a same variable. The original proof is quite intricate. J.-W. Klop and A. Middeldorp [13] give a simpler proof to the price of

an increased complexity. The case of linear, possibly overlapping rewrite systems was considered first by Toyama [22] and later shown decidable by Jouannaud and Sadfi [9]. M. Oyamaguchi defines *NV-sequentiality* a property intermediate between sequentiality and strong sequentiality, which is also decidable for orthogonal rewrite systems [15].

In this paper we use another quite simple approach, though less elementary: we show that the sequentiality of P is definable in SkS (resp. WSkS), the second-order monadic logic with k successors, provided that P is definable in SkS (resp. WSkS). It allows to easily derive all aforementioned decidability results. Relying on automata theory, the decidability of strong sequentiality (resp. NV-sequentiality) of possibly overlapping left linear rewrite systems becomes straightforward. This sheds new light on which properties of rewrite systems are indeed necessary in proving (NV-, strong-) sequentiality. Then, it becomes possible to derive new decidability results, for example NV-sequentiality for overlapping left linear rewrite systems or sequentiality of shallow linear rewrite systems. We may also add a *sort discipline* to the rewrite systems without loosing decidability.

This method has however several drawbacks: first, the complexity of SkS is non-ELEMENTARY, which is far too complex in general for “effective” methods. Second, for non-left linear rewrite system, the reducibility predicate is not expressible in SkS. Hence we cannot derive that strong sequentiality of R is expressible in SkS in such a case. Last, but not least, even if we know that the formula expressing the sequentiality of R is valid, how do we effectively find needed redexes in a term?

In order to answer these questions, we construct directly a tree automaton which accepts all terms that have a needed redex. By the well-known correspondence between WSkS and finite tree automata (see e.g. the survey [21]), we know in advance that such an automaton exists. Here, we show that it can be constructed in exponential time (for k fixed). This has several consequences. First, deciding strong sequentiality of any left linear rewrite system is in EXPTIME, since it reduces to an emptiness problem for tree automata, which can be decided in polynomial time. Then, the automaton which accepts all terms that have a needed redex yields directly the algorithm for searching needed redexes in a term.

There are still many issues to be investigated with profit in this framework: is strong sequentiality decidable for any (possibly non-linear) rewrite systems? Though automata with constraints [2, 3] cannot be used directly, we might consider some tree automata inspired by these definitions. What is the exact complexity of all decision questions in this area? We have only shown an EXPTIME inclusion. However there is no evidence that this is the best we can do. Also, what happens in the case of orthogonal rewrite systems? The automata should have a particular form, from which it might be possible to deduce more efficient procedures. Finally, we do not show how to *compile* an optimal reduction strategy, avoiding any backtrack in the input term, as done in [8]. Again, this should be possible from the tree automaton. Finally, other (sequential) reduction strategies as in [1] should also be investigated within this framework.

The paper is organized as follows: section 2 gives the definitions of an index and sequentiality and we recall the necessary background on SkS and tree automata. In section 3, we show how to express the sequentiality of a predicate P in SkS and apply this result to rewrite systems in section 4. In section 5 we construct directly the automaton accepting all terms that have an index (using the characterization of [13]) and derive extensions as well as complexity results. We also explain how an index search can be read on the automaton.

2 Basic Definitions

2.1 Terms

T is the set of terms built over a fixed alphabet \mathcal{F} of function symbols. Each $f \in \mathcal{F}$ comes with its *arity* $a(f)$, a nonnegative integer. Terms may also be viewed as labeled trees, i.e. mappings from a finite prefix-closed subset of words of positive integers (the *positions* in the tree) into \mathcal{F} , in such a way that the successors of a position p are exactly the strings $p \cdot i$ for $1 \leq i \leq a(f)$ when p is labeled with f . We will use the notations of [6]: $t|_p$ is the *subterm* at position p , $t[u]_p$ is the term obtained by replacing $t|_p$ with u . \mathcal{F} is assumed to be finite.¹

\mathcal{T}_Ω is the set of terms obtained by augmenting the set \mathcal{F} of function symbols with a new constant Ω (which stands intuitively for “unevaluated terms”). We assume that terms in \mathcal{T}_Ω always contain at least one occurrence of Ω . Such a set of terms is classically considered as the set of terms which are partially evaluated, i.e. terms in T which are “cut” on some branches.

Definition 2.1 *Let $t, u \in \mathcal{T}_\Omega$, $t \sqsubseteq u$ iff u can be obtained from t by replacing some occurrences of Ω in t with terms in \mathcal{T}_Ω .*

$s \sqsubseteq t$ intuitively means that “ t is more evaluated than s ”.

2.2 Sequentiality

Definition 2.2 (index,[8]) *Let P be a predicate on $\mathcal{T}_\Omega \cup T$. Let $t \in \mathcal{T}_\Omega$ and $p \in \text{Pos}(t)$. p is an index of P in t iff $t|_p = \Omega$ and*

$$\forall u \in \mathcal{T}_\Omega \cup T, (t \sqsubseteq u \wedge P(u) = \text{true}) \Rightarrow u|_p \neq \Omega$$

The set of indexes of a term $t \in \mathcal{T}_\Omega$ (which were also called *needed redexes* in the introduction) is written $\text{Index}(t)$. Intuitively, p is an index for P in t if, for all successful evaluations of t (the predicate P becomes true), the term at position p has been evaluated.

Definition 2.3 (sequentiality,[8]) *A predicate P on $\mathcal{T}_\Omega \cup T$ is sequential if*

$$\begin{aligned} \forall t \in \mathcal{T}_\Omega \cup T, (\exists u \in \mathcal{T}_\Omega \cup T, P(u) = \text{true} \wedge t \sqsubseteq u) \\ \Rightarrow (P(t) = \text{true} \vee \exists p \in \text{Pos}(t), p \in \text{Index}(t)) \end{aligned}$$

Intuitively, P is sequential if, for every partially evaluated term t such that P is false and P becomes true for some further evaluation of t , then there is an index of P in t .

¹Note that if one wants to consider terms with possibly infinitely many “variables” (actually constants, but we use the standard terminology), it is always possible to represent the variables $x_0, x_1, \dots, x_n, \dots$ using an additional constant x and an additional unary function symbol s ; they will be respectively represented by $x, s(x), \dots, s(s(\dots(s(x))\dots)), \dots$. In such a case, T is a regular subset of the set of all terms, but this does not cause any additional problem, as we will see later in the general case of typed terms. The status of variables in T (or \mathcal{T}_Ω) is different from the status of the variables in the rewrite system: the former are actually considered as constants along the evaluation process, while the latter may be instantiated since several distinct instances of the rules can be used.

2.3 Term Rewriting

\mathcal{X} is an infinite set of constant function symbols called *variables* and the set of terms build on $\mathcal{F} \cup \mathcal{X}$ is traditionally written $\mathcal{T}(\mathcal{F}, \mathcal{X})$. For any $s \in \mathcal{T}(\mathcal{F}, \mathcal{X})$, $\text{Var}(s)$ is the set of variables occurring in s . Substitutions are mappings from \mathcal{X} into $\mathcal{T}(\mathcal{F}, \mathcal{X})$, which are extended into endomorphisms of $\mathcal{T}(\mathcal{F}, \mathcal{X})$. We use the postfix notation for substitution applications.

A *term rewriting system* is a (finite) set of pairs of terms in $\mathcal{T}(\mathcal{F}, \mathcal{X})$, each pair (s, t) is written $s \rightarrow t$ (we do not require $\text{Var}(t) \subseteq \text{Var}(s)$). A term t *rewrites to* s through a rewrite system R , which is written $t \xrightarrow{R} s$ if there is a position p in t , a substitution σ and a rule $l \rightarrow r \in R$ such that $t|_p = l\sigma$ and $s = t[r\sigma]_p$. Rewriting using zero or many single rewriting steps, i.e. the reflexive transitive closure of \xrightarrow{R} is written $\xrightarrow{*}_R$.

2.4 Tree Automata

We recall here some basic definitions about tree automata (see e.g. [7]).

Definition 2.4 A finite (bottom-up) tree automaton consists of a ranked alphabet \mathcal{F} , a finite set of states Q , a subset Q_f of final states and a set of transition rules of the form $f(q_1, \dots, q_n) \rightarrow q$ where $f \in \mathcal{F}$, $n = a(f)$ and $q_1, \dots, q_n, q \in Q$ or $q \rightarrow q'$ where $q, q' \in Q$ (the latter transition rules are called ϵ -transitions). A tree automaton accepts t if t can be rewritten to a final state using the transition rules (see e.g. [7] for more details).

Definition 2.5 The language accepted by a tree automaton A is the set of terms t which are accepted by A .

A set L of trees is recognizable when there is a tree automaton A such that L is the language accepted by A .

Definition 2.6 A run of the automaton on a tree t is a mapping ρ from the positions of t into Q such that $\rho(p) = q$, $\rho(p \cdot 1) = q_1, \dots, \rho(p \cdot n) = q_n$ and $t(p) = f$ only if there is a transition rule $f(q_1, \dots, q_n) \rightarrow q'$ and a sequence of ϵ -transitions from q' to q . A run ρ is successful if $\rho(\Lambda)$ is a final state. t is accepted by A iff there is a successful run of A on t .

We will see in what follows several examples of recognizable sets of terms.

2.5 The logic (W)SkS

Missing definitions can be found in [21]. Terms of SkS are formed out of individual variables (x, y, z, \dots) , the empty string Λ and right concatenation with $1, \dots, k$. Atomic formulas are equations between terms, inequations $w < w'$ between terms or expressions " $w \in X$ " where w is a term and X is a (second-order) variable. Formulas are built from atomic formulas using the logical connectives $\wedge, \vee, \Rightarrow, \neg, \dots$ and the quantifiers \exists, \forall of both individual and second-order variables. Individual variables are interpreted as elements of $\{1, \dots, k\}^*$ and second-order variables as subsets of $\{1, \dots, k\}^*$. Equality is the string equality and inequality is the strict prefix ordering. In the *weak* second-order monadic logic WSkS, second-order variables only range over *finite* sets. Finite union and finite intersection, as well as inclusion and equality of sets are definable in (W)SkS in an obvious way. Hence we may use these additional connectives in the following.

The most remarkable result is the decidability of SkS (a result due to M. O. Rabin, see e.g. [17, 21] for comprehensive surveys). The main idea of the proof is to associate each formula ϕ whose free variables are X_1, \dots, X_n with a (Rabin) tree automaton which accepts the set

of n -uples of trees (or sets of strings) that satisfy the formula. Then decidability follows from closure and decidability properties of the corresponding class of tree languages. We only use here the weak case, in which only finite state tree automata are used. We will extensively use the following without any further mention:

Theorem 2.7 (Thatcher and Wright, 1969) *A set of finite trees is definable in WSkS iff it is recognized by a finite tree automaton.*

Formally, this correspondence needs to define a term in WSkS. We recall below how it can be done.

3 Relationship between Sequentiality and Recognizability

Let k be the maximal arity of a function symbol in \mathcal{F} and n be the cardinal of \mathcal{F} . A term t is represented in WSkS using $n + 2$ set variables X , X_Ω and $X_f, f \in \mathcal{F}$ (which will be written \vec{X} in the following). X will be the set of positions of t and X_Ω and each X_f will be the sets of positions that are labeled with the corresponding function symbol. We express in WSkS that some $n + 2$ -uple of finite sets of words are indeed encoding a term, which can be achieved using the formula

$$\begin{aligned} \text{Term}(\vec{X}) \stackrel{\text{def}}{=} & \\ & X = X_\Omega \cup \bigcup_{i=1}^n X_{f_i} \\ & \wedge \bigwedge_{i \neq j} (X_{f_i} \cap X_{f_j} = \emptyset \wedge X_\Omega \cap X_{f_i} = \emptyset) \\ & \wedge \forall x \in X, \forall y < x, y \in X \\ & \wedge \bigwedge_{f \in \mathcal{F} \cup \{\Omega\}} \forall x \in X_f, \bigwedge_{l=1}^{a(f)} x \cdot l \in X \bigwedge_{l=a(f)+1}^k x \cdot l \notin X \end{aligned}$$

In this setting, it is quite easy to express the sequentiality of P in (W)SkS as shown by the following lemmas.

Lemma 3.8 \sqsubseteq is definable in WSkS.

Proof

Assume that t, u are represented by \vec{X} and \vec{Y} respectively. Then $t \sqsubseteq u$ iff

$$X \subseteq Y \wedge \bigwedge_{f \in \mathcal{F}, f \neq \Omega} X_f \subseteq Y_f \quad \square$$

Lemma 3.9 Let P be a predicate on $\mathcal{T}_\Omega \cup T$ which is definable in (W)SkS. Then the set of terms in \mathcal{T}_Ω which have an index w.r.t. P is definable in (W)SkS.

Proof

Let $\phi(\vec{X})$ be the definition of P in (W)SkS. Then the set of terms which have an index is defined by translating definition 2.2:

$$\begin{aligned} \text{Index}(\vec{X}) \stackrel{\text{def}}{=} & \text{Term}(\vec{X}) \wedge \exists x \in X. x \in X_\Omega \wedge \forall \vec{Y}. \\ & (\text{Term}(\vec{Y}) \wedge \vec{X} \sqsubseteq \vec{Y} \wedge \phi(\vec{Y})) \Rightarrow x \in Y_\Omega \quad \square \end{aligned}$$

Theorem 3.10 *If P is definable in $(W)SkS$, then the sequentiality of P is decidable.*

Proof

Using the previous lemma and assuming that P is defined by $\phi(\vec{X})$, P is sequential iff the following formula holds:

$$\begin{aligned} \forall \vec{X}, (\text{Term}(\vec{X}) \wedge \exists \vec{Y}, \text{Term}(\vec{Y}) \wedge \phi(\vec{Y}) \wedge \vec{X} \sqsubseteq \vec{Y}) \\ \Rightarrow (\phi(\vec{X}) \vee \text{Index}(\vec{X})) \end{aligned}$$

which is a translation of definition 2.3. Then we conclude using Rabin's theorem [16, 17]. \square

4 Application to term rewriting systems

In this section, we show how to apply theorem 3.10 to various sequentiality results for term rewriting. We assume here the reader familiar with term rewriting (see e.g. [6] for missing definitions). We will say in particular that a term t is *linear* if each variable occurs at most once in t (A term is *shallow* if it is a variable or if all its variables occur at depth 1. A rewrite system R is *left linear* (resp. *linear*, resp. *shallow*) if all its left hand sides are linear (resp. all left and right hand sides are linear, resp. all left and right hand sides are shallow).

4.1 Strong sequentiality of left linear term rewriting systems

Let $N_{\mathcal{R}}$ be the predicate symbol on $\mathcal{T}_{\Omega} \cup T$ which holds true iff t has a normal form (w.r.t. \mathcal{R}) belonging to T .

Definition 4.11 ([8]) *A term rewriting system \mathcal{R} is sequential if the predicate $N_{\mathcal{R}}$ is sequential.*

This captures the intuitive notion sketched in introduction: when \mathcal{R} is sequential, then there is an optimal reduction strategy. Since sequentiality of \mathcal{R} is undecidable in general, a sufficient condition for sequentiality (called strong sequentiality) has been introduced in [8].

Let $\text{Red}_{\mathcal{R}}$ be the predicate symbol on $\mathcal{T}_{\Omega} \cup T$ which holds true iff t is reducible by \mathcal{R} .

Definition 4.12 ([8]) *A term rewriting system \mathcal{R} is strongly sequential if the predicate $\text{Red}_{\mathcal{R}}$ is sequential.*

Lemma 4.13 *When \mathcal{R} is left linear, $\text{Red}_{\mathcal{R}}$ is recognized by a finite bottom-up tree automaton.*

Proof

For each non-variable strict subterm u of a left hand side of a rule, consider a state q_u . In addition, we have a state q_r (the final state, or the state in which we know that the term is reducible) and the state q_{\top} which accepts all terms. Then, to each $u = f(u_1, \dots, u_n)$, we associate the production rule $f(q_{u_1}, \dots, q_{u_n}) \rightarrow q_u$ where q_{u_i} is understood as q_{\top} when u_i is a variable. To each left hand side of a rule $l = f(t_1, \dots, t_n)$, we associate the rule $f(q_{t_1}, \dots, q_{t_n}) \rightarrow q_r$ and the states q_r are propagated: we have the rules $f(q_{\top}, \dots, q_{\top}, q_r, q_{\top}, \dots, q_{\top}) \rightarrow q_r$ for all function symbols f . Finally, if not already present, we add the rules $f(q_{\top}, \dots, q_{\top}) \rightarrow q_{\top}$. \square

This yields as an easy consequence the following (known from [9]) decidability result:

Corollary 4.14 *The strong sequentiality of left linear (possibly overlapping) rewrite systems is decidable.*

Proof

This is a consequence of lemma 4.13 and theorem 3.10 since recognizable sets of terms are definable in WSkS [20]. \square

Note that this doesn't work for non-left linear rewrite systems because then $\text{Red}_{\mathcal{R}}$ is not definable by a finite bottom-up tree automaton: we need disequality tests. Actually, adding the corresponding tests to the logic (W)SkS yields an undecidable logic.

Another consequence of lemma 4.13 is the recognizability of the set of irreducible terms in $T(\mathcal{F})$: this is a consequence of the closure property of recognizable tree languages by complement. Let us show however an explicit construction of such an automaton, since we will re-use it for further analysis in the following.

Given two terms $s, t \in T(\mathcal{F}, \mathcal{X})$, we write $s \downarrow t$ for a most general unifier (when it exists) of s and a renaming t' of t such that t' and s do not share variables. Given a left linear rewrite system \mathcal{R} , let $S(\mathcal{R})$ be the set of strict subterms of the left hand sides of \mathcal{R} , up to similarity, which we close under \downarrow . (This may yield an exponential number of terms in $S(\mathcal{R})$: one for each set of subterms of the lhs of \mathcal{R}). With each term t in $S(\mathcal{R})$, which is not an instance of a lhs of \mathcal{R} , we associate a state q_t . (we write q_x the state associated with all variables. We assume that q_x is in the set of states). Let $Q = \{q_t \mid t \in S(\mathcal{R})\} \cup \{q_r\}$ and Q_f be all states but q_r . Intuitively, all reducible terms will be accepted in q_r . The terms accepted in a state q_t will be all instances of t that are not instances of any $q_{t\sigma}$. More precisely, we consider the following set of production rules:

$$\begin{aligned}
 f(q_{t_1}, \dots, q_{t_n}) &\rightarrow q_t \\
 &\quad \text{If } f(t_1, \dots, t_n) \text{ is an instance of } t \\
 &\quad \text{and not an instance of some } t\sigma \text{ s.t. } q_{t\sigma} \in Q \\
 f(q_{t_1}, \dots, q_{t_n}) &\rightarrow q_r \\
 &\quad \text{If } f(t_1, \dots, t_n) \text{ is an instance} \\
 &\quad \text{of some lhs of } \mathcal{R} \\
 f(q_1, \dots, q_n) &\rightarrow q_r \\
 &\quad \text{If } q_r \in \{q_1, \dots, q_n\}
 \end{aligned}$$

Let us call $\mathcal{A}_{NF(\mathcal{R})}$ the above constructed automaton.

Example 1

$$R = \begin{cases} h(x) \rightarrow g(f(a, a)) \\ f(x, a) \rightarrow a \\ f(g(a), x) \rightarrow f(x, g(a)) \end{cases}$$

The automaton $\mathcal{A}_{NF(R)}$ consists of the production rules (assuming for simplicity that there are no additional function symbols besides h, f, g, a)

$$\begin{array}{ll}
 a \rightarrow q_a & g(q_a) \rightarrow q_{g(a)} \\
 f(q_a, q_a) \rightarrow q_r & h(q_a) \rightarrow q_r \\
 f(q_a, q_{g(a)}) \rightarrow q_x & f(q_{g(a)}, q_a) \rightarrow q_r \\
 f(q_{g(a)}, q_{g(a)}) \rightarrow q_r & h(q_{g(a)}) \rightarrow q_r \\
 g(q_{g(a)}) \rightarrow q_x & f(q_x, q_a) \rightarrow q_r \\
 f(q_x, q_{g(a)}) \rightarrow q_x & f(q_x, q_x) \rightarrow q_x \\
 f(q_a, q_x) \rightarrow q_x & f(q_{g(a)}, q_x) \rightarrow q_r \\
 h(q_x) \rightarrow q_r & g(q_x) \rightarrow q_x \\
 f(q_r, q) \rightarrow q_r & f(q, q_r) \rightarrow q_r \\
 g(q_r) \rightarrow q_r & h(q_r) \rightarrow q_r
 \end{array}$$

where q stands for any state. Final states will be $q_a, q_{g(a)}, q_x$.

Lemma 4.15 $\mathcal{A}_{NF(R)}$ accepts the set of irreducible terms in $T(\mathcal{F})$. This automaton is deterministic and completely specified.

Proof

The automaton is deterministic since, assuming that $f(t_1, \dots, t_n)$ is an instance of both t and u ($t, u \in S(\mathcal{R})$), then it is an instance of $t \downarrow u$, hence the only rule which can be applied to $f(q_{t_1}, \dots, q_{t_n})$ is either $f(q_{t_1}, \dots, q_{t_n}) \rightarrow q_r$ (when $f(t_1, \dots, t_n)$ is an instance of a lhs of \mathcal{R}) or $f(q_{t_1}, \dots, q_{t_n}) \rightarrow q_{u_1 \downarrow \dots \downarrow u_m}$ if $\{u_1, \dots, u_m\}$ is the set of terms in $S(\mathcal{R})$ which are not instances of a lhs of R and such that $f(t_1, \dots, t_n)$ is an instance of each u_i (and not an instance of a lhs).

The automaton is completely specified since every term is (at least) an instance of x . Then either one of its direct subterms is accepted in state q_r , or it is itself accepted in state q_r , or there is a state q_t in which it is accepted.

We show by induction on the size of u that u is accepted in the state q_t iff u is not reducible, it is an instance of t and not an instance of some other $t\sigma \in S(\mathcal{R})$. If u is a constant, then either $u \in S(\mathcal{R})$ (in which case it is accepted in state q_r or q_a depending on its reducibility) or it is accepted in state q_x . Now, consider a term $t = f(t_1, \dots, t_n)$. If some t_i is reducible, then it is accepted in state q_r by induction hypothesis and t is accepted in state q_r too. Otherwise, by induction hypothesis, for every i , t_i is accepted in state q_{u_i} s.t. $t_i = u_i\sigma_i$ and t_i is not an instance of any other $u_i\sigma$. Then either t is reducible, hence an instance of a lhs of a rule, and it is accepted in state q_r , or else, there is a rule $f(q_{u_1}, \dots, q_{u_n}) \rightarrow q_u$ such that t is accepted in state q_u , $f(u_1, \dots, u_n)$ is an instance of u and not an instance of any other $u\sigma$. Then, if $t = f(v_1, \dots, v_n)\sigma$ for some σ , $t_i = v_i\sigma$ for all i . Hence, for all i , u_i is an instance of v_i , which implies that $f(v_1, \dots, v_n)$ is an instance of u (assuming the disjointness of variables).

It follows that t is reducible iff it is accepted in the state q_r , hence it is irreducible iff it is accepted in another state, thanks to determinism and complete specification. \square

These constructions can be simplified for a particular class of rewrite system:

Lemma 4.16 Assume that for any two strict subterms s, t of some left hand side(s) of R , if s and t are unifiable, then either s is an instance of t or t is an instance of s . Then Red and $NF(R)$ are accepted by deterministic bottom-up tree automata with $O(|R|)$ states.

This is a direct consequence of the construction of $\mathcal{A}_{NF(R)}$: the set of states is $O(|R|)$ in this case.

4.2 Sequentiality of shallow linear rewrite systems

Lemma 4.17 *If \mathcal{R} is a shallow linear rewrite system, then $N_{\mathcal{R}}$ is recognized by a finite tree automaton.*

Proof

We start with the automaton $\mathcal{A}_{NF(\mathcal{R})}$ which accepts the set of irreducible terms in $T(\mathcal{F})$ (thanks to lemma 4.15). Then we complete it in such a way that for every ground term t occurring in a right side of \mathcal{R} there is a state q_t which accepts t (and only this term), and a state q_{\top} which accepts all terms in $\mathcal{T}_{\Omega} \cup T$. (This differs from q_x in which all terms of T are accepted). Let \mathcal{A} be the resulting automaton.

Then, we build an automaton \mathcal{A}_1 which accepts all terms in $T \cup \mathcal{T}_{\Omega}$ that have a normal form in T . For, we use the same set of states as \mathcal{A} (and the same set of final states). We start with the set P of production rules of \mathcal{A} and saturate P using the following set of inference rules:

$$\frac{f(t_1, \dots, t_n) \rightarrow g(u_1, \dots, u_m) \in R \quad g(q_1, \dots, q_m) \rightarrow q \in P}{f(q'_1, \dots, q'_n) \rightarrow q \in P}$$

If

- when u_i is a ground term, then u_i is accepted in state q_i (by the current automaton)
- $q'_i = q_j$ whenever $t_i = u_j$
- $q'_i = q_{t_i}$ when $t_i \in T$
- $q'_i = q_{\top}$ when t_i is a variable not occurring in the right side of the rule

and

$$\frac{f(t_1, \dots, t_n) \rightarrow x \in R \quad q \in Q}{f(q_1, \dots, q_n) \rightarrow q \in P}$$

If

- x is a variable
- $q_i = q$ whenever $t_i = x$
- $q_i = q_{t_i}$ whenever t_i is a ground term.
- $q_i = q_{\top}$ when t_i is a variable distinct from x .

This terminates since the set of states being fixed, the number of possible inferred production rules is bounded. It yields a finite bottom-up tree automaton accepting all terms in $T \cup \mathcal{T}_{\Omega}$ that have a normal form in T . There are two inclusions to prove:

All terms accepted by \mathcal{A}_1 do have a normal form in T .

This is proved by induction on the number of times the above inference rules have been applied. If they cannot be applied, then the inclusion follows from lemma 4.13. Otherwise, consider the automaton \mathcal{A}_N^* computed after N inference steps and assume that \mathcal{A}_N^* only accepts terms that have a normal form. Let \mathcal{A}_{N+1}^* be the automaton obtained by augmenting the set of production rules of \mathcal{A}_N^* with the rule $r \stackrel{\text{def}}{=} f(q'_1, \dots, q'_n) \rightarrow q$ following the conditions of one of the inference rules. Assume $t \xrightarrow[\mathcal{A}_{N+1}^*]{*} q_f$ with $q_f \in Q_f$. We prove

by induction on the number of times r is applied in this reduction that t has a normal form. If r is not applied at all, then $t \xrightarrow[\mathcal{A}_N^*]{*} q_f$ and, by hypothesis, t has a normal form. Now, if $t \xrightarrow[\mathcal{A}_N^*]{*} t_1 \xrightarrow[r]{*} t_2 \xrightarrow[\mathcal{A}_{N+1}^*]{*} q_f$, then there is a position p of t_1 such that $t_1|_p = f(q'_1, \dots, q'_n)$ and $t_2|_p = q$.

We investigate now the possible constructions of r :

First inference rule We build a term u as follows: $u = t[g(u_1, \dots, u_m)]_p$ where $u_j = t|_{p \cdot i}$ whenever $q'_i = q_j$ and $u_j = v$ whenever $q_j = q_v$ (for v a ground term). Then $t \xrightarrow[R]{*} u$.

On the other hand, $u \xrightarrow[\mathcal{A}_N^*]{*} t_2$, by construction of r and since for every $i = 1, \dots, n$,

$t|_{p \cdot i} \xrightarrow[\mathcal{A}_N^*]{*} q'_i$. Hence, by induction hypothesis, u has a normal form in T . Now, since $t \xrightarrow[R]{*} u$, t has also a normal form in T .

Second inference rule We proceed in a similar way: we let $u = t[t|_{p \cdot i}]_p \xrightarrow[R]{*} u$.

$t|_{p \cdot i} \xrightarrow[\mathcal{A}_N^*]{*} q_i$ and $q_i = q$. Hence $u \xrightarrow[\mathcal{A}_N^*]{*} t_2$ by construction. Now, using the induction hypothesis on u , u has a normal form in T , and t has a normal form in T too since $t \xrightarrow[R]{*} u$.

All terms that do have a normal form in T are accepted by \mathcal{A}_1 . This is proved by induction on length of the reduction of t to one of its normal forms in T . If t is in normal form, then, by definition of \mathcal{A}_1 , t is accepted. If $t \xrightarrow[N+1]{R} t'$ and $t' \in NF$, then let $t \xrightarrow[R]{N} t_1 \xrightarrow[R]{*} t'$. Let $t|_p = f(l_1, \dots, l_n)\sigma$ and $t_1 = t[g(r_1, \dots, r_m)\sigma]_p$ for some rewrite rule $f(l_1, \dots, l_n) \rightarrow g(r_1, \dots, r_m) \in R$ (the case where r is a variable is similar). By induction hypothesis, t_1 is accepted by \mathcal{A}_1 . Let us consider a successful run of the automaton on t_1 :

$$t_1 \xrightarrow[\mathcal{A}_1^*]{*} t_1[g(q_1, \dots, q_m)]_p \xrightarrow[g(q_1, \dots, q_m) \rightarrow q]{} t_1[q]_p \xrightarrow[\mathcal{A}_1^*]{*} q_f$$

and $q_f \in Q_f$. By construction of \mathcal{A}_1 , there is a production rule $r \stackrel{\text{def}}{=} f(q'_1, \dots, q'_n) \rightarrow q$ in P such that r_i is accepted in state q_i when r_i is a ground term, $q'_i = q_j$ whenever $t_i = u_j$, $q'_i = q_l$ when l_i is ground and $q'_i = q_\top$ when l_i is a variable which does not occur in $g(r_1, \dots, r_m)$. Then there is a reduction of each $t|_{p \cdot i}$ to q'_i :

- if l_i is a variable which does not occur in r , then $l_i\sigma \xrightarrow[\mathcal{A}_1^*]{*} q_\top$ by definition of q_\top
- if $l_i \in T$, then $l_i \xrightarrow[\mathcal{A}_1^*]{*} q_l$ by definition of q_l
- if l_i is a variable and $l_i = r_j$ for some j , then $l_i\sigma = r_j\sigma$ and hence $l_i\sigma \xrightarrow[\mathcal{A}_1^*]{*} q_j = q'_i$

Now, there is a reduction of $t|_p$ to $f(q'_1, \dots, q'_n)$, yielding the desired $t \xrightarrow[\mathcal{A}_1^*]{*} t_1[q]_p$.

Finally, we intersect \mathcal{A}_1 with \mathcal{T}_Ω (which is obviously recognizable). \square

Let us show an example of the automaton accepting all terms that can be reduced to a normal form.

Example 2 We use the example 1. In what follows, for sake of simplicity, we will not consider the rules which involve a state q_r (they do not play any role).

We add first the rules:

$$\begin{array}{llll} f(q_a, q_a) & \rightarrow & q_{f(a,a)} & g(q_{f(a,a)}) \rightarrow q_{g(f(a,a))} & a & \rightarrow & q_\top \\ g(q_\top) & \rightarrow & q_\top & h(q_\top) & \rightarrow & q_\top & f(q_\top, q_\top) \rightarrow q_\top \\ \Omega & \rightarrow & q_\top & & & & \end{array}$$

Now, we start the saturation process, yielding to the new rules (in order of computation, and excluding the rules yielding q_\top which are irrelevant):

$$\begin{array}{llll} h(q_\top) & \rightarrow & q_{g(f(a,a))} & f(q_\top, q_a) \rightarrow q_a & f(q_{g(a)}, q_x) \rightarrow q_x \\ f(q_{g(a)}, q_a) & \rightarrow & q_x & h(q_\top) & \rightarrow & q_{g(a)} \end{array}$$

This last rule is obtained after noticing that $f(a, a) \xrightarrow{*} q_a$, hence from $h(x) \rightarrow g(f(a, a)) \in R$ and $g(q_a) \rightarrow q_{g(a)}$, we can deduce $h(q_\top) \rightarrow q_{g(a)}$.

Let us consider two examples of computations using the resulting automaton:

$$h(\Omega) \rightarrow h(q_\top) \rightarrow q_{g(a)}$$

hence $h(\Omega)$ is accepted by the automaton.

$$f(g(a), \Omega) \rightarrow f(g(q_a), \Omega) \rightarrow f(g(q_a), q_\top) \rightarrow f(q_{g(a)}, q_\top)$$

the reduction cannot be continued any longer (except by going to q_\top). Moreover, there is no other computation sequence: $f(g(a), \Omega)$ is not accepted.

As a consequence of theorem 3.10 and lemma 4.17 we have the new decidability result:

Corollary 4.18 *The sequentiality of shallow linear rewrite systems is decidable.*

4.3 NV-sequentiality of linear rewrite systems

Oyamaguchi has shown in [15] that sequentiality is decidable for linear rewrite systems such that the left and right hand sides do not share variables. A linear rewrite system R is then called *NV-sequential* if, when renaming the variables of the right hand sides in such a way that they do not share any more variables with the left hand sides, then we get a sequential rewrite system R_V . It turns out that NV-sequentiality is again definable in WSkS (without the orthogonality assumption of [15]).

Lemma 4.19 *For any linear rewrite system R , N_{R_V} is definable in WSkS.*

Proof

We only have to prove that N_{R_V} is recognized by a finite tree automaton. We start with the automaton of lemma 4.15 and add a state q_t for each subterm t of a right hand side of R_V , up to literal similarity. (If this state is not already present). We also add production rules in such a way that the set of terms accepted in such a state q_t is the set of instances (in T) of t . In addition, we consider states q'_t , for each strict subterm t of a left hand side of R_V , up to literal similarity. We add the production rules in such a way that the terms accepted in state q'_t are the instances in $T_\Omega \cup T$ of t . Let us call again \mathcal{A} the resulting automaton; its final states are the final states of $\mathcal{A}_{NF(R_V)}$. Of course \mathcal{A} is now non-deterministic.

We saturate \mathcal{A} with the following inference rules:

$$\frac{g(l_1, \dots, l_n) \rightarrow f(r_1, \dots, r_m) \in R_V \quad f(q_1^*, \dots, q_m^*) \rightarrow q^* \in P}{g(q'_1, \dots, q'_n) \rightarrow q^* \in P}$$

If, for every i there is an instance of r_i which is accepted in state q_i^* and q_i^* is either q_i or q'_i (Note that this condition is decidable as the set of instances of r_i is accepted by a finite tree automaton and by decision properties for tree automata).

$$\frac{g(l_1, \dots, l_n) \rightarrow x \in R_V \quad q^* \in Q}{g(q'_1, \dots, q'_n) \rightarrow q^* \in P}$$

If x is a variable and q^* is either q or q' .

The saturation process does terminate since no new state is added.

We claim that the resulting automaton accepts the terms of $T \cup \mathcal{T}_\Omega$ that have a normal form in T . For, we have two inclusions to prove.

Any term accepted by \mathcal{A} can be reduced to a normal form in T Let \mathcal{A}_N be the automaton obtained after applying N inference steps. We prove, by induction on N that \mathcal{A}_N only accepts terms in $\mathcal{T}_\Omega \cup T$ that have a normal form in T . If $N = 0$, then by lemma 4.15, the automaton accepts the terms that are in normal form in T . Now, assume we obtain \mathcal{A}_{N+1} by adding a new rule r (using, say, the first inference rule). Let t be a term accepted by

\mathcal{A}_{N+1} : $t \xrightarrow[\mathcal{A}_{N+1}]{} q_f \in Q_f$. We prove, by induction on the number of times r is used in

this reduction, that t has a normal form in T . If r is not used at all, $t \xrightarrow[\mathcal{A}_N]{} q_f$ and, by

hypothesis on \mathcal{A}_N , t has a normal form in T . Now, assume that $t \xrightarrow[\mathcal{A}_N]{} t_1 \xrightarrow[r]{} t_2 \xrightarrow[\mathcal{A}_{N+1}]{} q_f$.

Let r be $g(q'_1, \dots, q'_n) \rightarrow q^*$, $t_1|_p = g(q'_1, \dots, q'_n)$ and $t_2 = t_1[q^*]_p$. By construction, there is a rule $g(l_1, \dots, l_n) \rightarrow f(r_1, \dots, r_m)$ in R_V , a production rule $f(q_1, \dots, q_n) \rightarrow q$ in \mathcal{A}_N and, for each i , a term u_i which is an instance of r_i accepted in state q_i^* . Now, let u be $t[f(u_1, \dots, u_m)]_p$. $u \xrightarrow[\mathcal{A}_N]{} t_2$ and hence u has a normal form in T by induction hypothesis.

Moreover, $t \xrightarrow[g(l_1, \dots, l_n) \rightarrow f(r_1, \dots, r_m)]{} u$ since the variables of the right and left hand sides are disjoint. Hence t has a normal form in T .

Any term that can be reduced to a normal form in T is accepted by \mathcal{A} We prove this result by induction on the length of the reduction sequence from t to one of its normal form in T . If this length is 0, then t is accepted by the automaton $\mathcal{A}_{NF(R_V)}$ and hence by \mathcal{A} . Now assume that $t \xrightarrow[g(l_1, \dots, l_n) \rightarrow f(r_1, \dots, r_m)]{} u$: $t|_p = g(l_1\sigma, \dots, l_n\sigma)$ and $u = t[f(r_1\theta, \dots, r_m\theta)]_p$.

By induction hypothesis, u is accepted by \mathcal{A} :

$$u \xrightarrow[\mathcal{A}]{} u[f(q_1^*, \dots, q_m^*)]_p \xrightarrow[f(q_1, \dots, q_m) \rightarrow q]{} u[q^*]_p \xrightarrow[\mathcal{A}]{} q_f$$

By definition, for each i , there is an instance of r_i ($r_i\theta$) which is accepted in state q_i^* . Hence, using the first inference rule, there is production rule $g(q'_1, \dots, q'_n) \rightarrow q^* \in P$.

Now, for each i , $l_i\sigma \xrightarrow[\mathcal{A}]{} q'_i$, hence $t|_p \xrightarrow[\mathcal{A}]{} q^*$ and t is accepted by the automaton.

□

Example 3 Let us consider the very simple example:

$$R = \begin{cases} h(h(x)) \rightarrow f(g(x)) \\ g(x) \rightarrow h(a) \\ f(a) \rightarrow f(a) \end{cases}$$

In the system R_V , the variable on the right side of the first rule is replaced with another variable y .

The automaton $\mathcal{A}_{NF(R)}$ contains, besides the rules yielding q_r , the following productions:

$$\begin{array}{lll} a \rightarrow q_a & h(q_a) \rightarrow q_{h(x)} & f(q_{h(x)}) \rightarrow q_x \\ h(q_x) \rightarrow q_x & f(q_x) \rightarrow q_x & \end{array}$$

Final states will be $q_a, q_{h(a)}$ and q_x .

We add the following production rules:

$$\begin{array}{lll} h(q_a) \rightarrow q_{h(a)} & f(q_a) \rightarrow q_{f(a)} & a \rightarrow q_\top \\ h(q_\top) \rightarrow q_\top & f(q_\top) \rightarrow q_\top & g(q_\top) \rightarrow q_\top \\ g(q_\top) \rightarrow q_{g(x)} & \Omega \rightarrow q'_x & a \rightarrow q'_x \\ h(q'_x) \rightarrow q'_x & g(q'_x) \rightarrow q'_x & f(q'_x) \rightarrow q'_x \\ h(q'_x) \rightarrow q'_{h(x)} & a \rightarrow q'_a & \end{array}$$

We arrive at the saturation process which produces the following rules (we exclude the rules yielding q_\top):

$$\begin{array}{lll} h(q'_{h(x)}) \rightarrow q'_x & g(q'_x) \rightarrow q_{h(x)} & g(q'_x) \rightarrow q_{h(a)} \\ g(q'_x) \rightarrow q'_{h(x)} & h(q'_{h(x)}) \rightarrow q_x & \end{array}$$

The last rule is obtained as follows: there is an instance of $g(y)$ which is accepted in state $q_{h(x)}$ (thanks to the rule $g(q'_x) \rightarrow q_{h(x)}$). Hence, from the rules $h(h(x)) \rightarrow f(g(y))$ and $f(q_{h(x)}) \rightarrow q_x$, we deduce $h(q'_{h(x)}) \rightarrow q_x$.

Corollary 4.20 *NV-sequentiality is decidable for left linear (possibly overlapping) rewrite systems.*

Proof

This is a consequence of theorem 3.10 and lemma 4.19. \square

Note that this gives a much simpler proof than in [15], and in a more general case. We could also prove this result using ideas similar to [5].

4.4 Sorted systems

All above results can be extended to *order-sorted rewrite systems*. In such systems, variables are restricted to range over some regular sets of trees². In particular, we find again some decidability results of [12] as well as their extension to arbitrary left-linear rewrite systems.

²Order-sorted signatures, which include subsort declarations and overloading are exactly tree automata, as noticed e.g. in [4]

5 Direct construction of the automaton

For reasons which have already been explained, we construct here directly the automaton accepting all terms that have an index w.r.t $\text{Red}_{\mathcal{R}}$. We only consider left linear rewrite systems.

For the direct construction of automata, it is more convenient to use the formalism of [13]. Of course, we could construct an automaton using the correspondence between automata and logic, but this construction would be too complex.

5.1 Another characterization of indexes

Let $t \in \mathcal{T}(\mathcal{F} \cup \{\Omega\}, \mathcal{X})$ and $u \in \mathcal{T}(\mathcal{F}, \mathcal{X})$. We say that t is *compatible* with u if there is some instance v of u such that $t \sqsubseteq v$. Let R be a rewrite system. Then $\xrightarrow{R_{\Omega}}$ is the relation on \mathcal{T}_{Ω} defined by $t \xrightarrow{R_{\Omega}} u$ iff there is a $p \in \text{Pos}(t)$ such that $t|_p \neq \Omega$ and $t|_p$ is compatible with some left hand side of a rule and $u = t[\Omega]_p$. $\xrightarrow{R_{\Omega}}$ is a convergent reduction relation. The normal form of a term t w.r.t to $\xrightarrow{R_{\Omega}}$ is written $t \downarrow_{R_{\Omega}}$.

Theorem 5.21 ([13]) *Let $x \in \mathcal{X}$. The position p such that $t|_p = \Omega$ is an index of t (w.r.t. $\text{Red}_{\mathcal{R}}$) iff $(t[x]_p \downarrow_{R_{\Omega}})|_p = x$.*

5.2 Construction of the automaton $\mathcal{A}_{\text{noind}}$

We construct first an automaton accepting the set of terms which that can be reduced to Ω by R_{Ω} .

Lemma 5.22 *For every linear rewrite system, there is an automaton $\mathcal{A}_{R_{\Omega}}$ with $O(|R|)$ states which recognizes the set of terms $t \in \mathcal{T}_{\Omega}$ that can be reduced to Ω using R_{Ω} .*

Actually this lemma can be seen as a particular case of lemma 4.19. Let us however show a slightly different construction in detail since we will need additional properties.

Proof

With each strict subterm t of a left hand side of a rule (up to literal similarity), we associate a state q_t . In addition, we have the final state q_{Ω} and, if necessary, the state q_x (x is a variable). Then, for each $f \in \mathcal{F}$ and each q_{t_1}, \dots, q_{t_n} , we add the production rules

S1: $f(q_{t_1}, \dots, q_{t_n}) \rightarrow q_u$ if $f \neq \Omega$, $f(t_1, \dots, t_n)$ is compatible with u and q_u is in the set of states.

S2: $f(q_{t_1}, \dots, q_{t_n}) \rightarrow q_{\Omega}$ if, $f(t_1, \dots, t_n)$ is compatible with a left hand side of a rule

S3: $\Omega \rightarrow q_{\Omega}$

The number of states in $\mathcal{A}_{R_{\Omega}}$ is $O(|R|)$ and the number of rules is $O(|R|^{k+1})$ where k is the maximal arity of a function symbol.

We have now to show two inclusions.

Every term accepted by $\mathcal{A}_{R_{\Omega}}$ can be reduced to Ω by R_{Ω} . We prove, by induction on the length of the reduction (i.e. the size of t) that, if $t \xrightarrow{\mathcal{A}_{R_{\Omega}}} q_u$ then $t \xrightarrow{R_{\Omega}} u$. When the length is 1, t is a constant and $t = u$.

Assume now that $f(t_1, \dots, t_n) \xrightarrow[\mathcal{A}_{R_\Omega}]{*} f(q_{u_1}, \dots, q_{u_n}) \xrightarrow[\mathcal{A}_{R_\Omega}]{} q_u$. By induction hypothesis, for every i , $t_i \xrightarrow[\mathcal{A}_{R_\Omega}]{*} u_i$. Moreover, $f(u_1, \dots, u_n) \xrightarrow[\mathcal{A}_{R_\Omega}]{} u$, by definition of R_Ω and properties of the rules.

Every term in \mathcal{T}_Ω that can be reduced to Ω by R_Ω is accepted by \mathcal{A}_{R_Ω} . We prove this part by induction on the length of the reduction to Ω . If the term t is Ω itself, then there is nothing to prove. If $t \xrightarrow[\mathcal{A}_{R_\Omega}]{*} u \xrightarrow[\mathcal{A}_{R_\Omega}]{*} \Omega$, by induction hypothesis $u \xrightarrow[\mathcal{A}_{R_\Omega}]{*} q_\Omega$. Let $u = t[\Omega]_p$ and $t|_p \xrightarrow[\mathcal{A}_{R_\Omega}]{} \Omega$. By definition of R_Ω , this means that replacing Ω 's with terms in $t|_p$ we get an instance $l\sigma$ of a left hand side of a rule l . $l\sigma$ itself is accepted in state q_Ω by construction. Let ρ_1 be a successful run of the automaton on $l\sigma$. Now, we construct a run on $t|_p$ as follows: if p' is a position of both $l\sigma$ and $t|_p$ and $t(p \cdot p') = l\sigma(p')$, then we let $\rho(p') = \rho_1(p')$. Otherwise, by hypothesis, we have $t(p \cdot p') = \Omega$, in which case, we let $\rho(p') = q_\Omega$. ρ is a run indeed.

□

Note that \mathcal{A}_{R_Ω} is in general non-deterministic and that determinizing it may require exponentially many states. For example, if $g(f(x, a))$ and $h(f(x, b))$ are two left members of R , from $f(q_x, q_\Omega)$ we can reach the two states $q_{f(x, a)}$ and $q_{f(x, b)}$ and we cannot commit to any of them before knowing what is the symbol above. One way to prevent this situation is to add, for every subterm of a left hand side of a rule a state for each term obtained by replacing some subterms of t with Ω . But this step is exponential. It is not, in principle, better than determinizing \mathcal{A}_{R_Ω} . Following this, it is possible to compute an automaton \mathcal{A}_{ind} which accepts all terms that have an index. The automaton would be non-deterministic and contain exponentially many states. We will show its construction later on. However, for the decision problem, we need to decide whether all irreducible terms in \mathcal{T}_Ω are accepted by \mathcal{A}_{ind} . This question can only be decided in exponential time w.r.t. the number of states of the automaton (automata inclusion is EXPTIME-complete when the right member of the inclusion can be non-deterministic [18]). This would yield a doubly exponential test. It is however possible to reduce the complexity to a single exponential, computing directly an automaton for the complement of \mathcal{A}_{ind} and deciding its inclusion in the set of reducible terms. That is what we are doing now.

Lemma 5.23 *For every left linear rewrite system R , it is possible to compute in $O(2^{|R|})$ time an automaton \mathcal{A}_{noind} which accepts the terms $t \in \mathcal{T}_\Omega$ that do not have an index.*

Proof

Let Q_{R_Ω} be the set of states of \mathcal{A}_{R_Ω} . The states Q of our automaton will consist of pairs of subsets of Q_{R_Ω} . The first components of such pairs will be written as disjunctions of states $q_1 \vee \dots \vee q_n$, whereas the second components will be written as conjunction of states $q_1 \wedge \dots \wedge q_n$. The final states will be pairs $[S; \emptyset]$. Intuitively, the second component in the pair correspond to terms that have to be "eliminated" by R_Ω .

The production rules are defined as follows: first the rule for Ω is

$$\Omega \rightarrow [\{q_\Omega\}, \{q_x\}]$$

On the first component, we will find the behaviour of the automaton as in \mathcal{A}_{R_Ω} . The second component correspond to index guess: if Ω has been replaced with x , we enter the state q_x .

The progression rules are defined as follows:

$$f([S_1; S'_1], \dots, [S_n; S'_n]) \rightarrow [S; S']$$

if

- $S = \{q \mid \forall i = 1 \dots n, \exists t_i \in S_i, f(q_{t_1}, \dots, q_{t_n}) \xrightarrow{\mathcal{A}_{R_\Omega}} q\}$
- $S' = \{\phi(t', i) \mid (t', i) \in E\}$ where ϕ is a mapping from E to states such that

$$f(q_{t_1}, \dots, q_{t_{i-1}}, q_{t'}, q_{t_{i+1}}, \dots, q_{t_n}) \xrightarrow{\mathcal{A}_{R_\Omega}} \phi(t', i)$$

for some q_{t_1}, \dots, q_{t_n} belonging respectively to S_1, \dots, S_n .

- E is the set of pairs (t', i) , $i = 1 \dots n$, $t' \in S'_i$ such that there is no states q_{t_1}, \dots, q_{t_n} belonging to S_1, \dots, S_n respectively such that $f(q_{t_1}, \dots, q_{t_{i-1}}, q_{t'}, q_{t_{i+1}}, \dots, q_{t_n}) \xrightarrow{\mathcal{A}_{R_\Omega}} q_\Omega$.

Intuitively, in the first component we record all possible behaviours of \mathcal{A}_{R_Ω} , whereas in the second component, we superpose all behaviours corresponding to all index guesses.

We claim that a term $t \in \mathcal{T}_\Omega$ is accepted by this automaton iff it has no index, i.e. iff for all positions p of Ω in t , $p \notin \text{Pos}((t[x]_p) \downarrow_{R_\Omega})$.

We have to prove two inclusions.

If $t \in \mathcal{T}_\Omega$ is accepted by \mathcal{A} , then t has no index

First note that, by construction, $t \xrightarrow[\mathcal{A}]{*} [S; S']$ for some S' iff $t \xrightarrow[\mathcal{A}_{R_\Omega}]{*} q_u$ for all $q_u \in S$.

Assume $t \xrightarrow[\mathcal{A}]{*} [S; \emptyset]$. Let p be a position of Ω in t . We will show that there is prefix p' of p such that $t[x]_{p'} \xrightarrow[\mathcal{R}_\Omega]{*} \Omega$. More precisely, let $T_{\Omega, x}$ be the set of terms in $\mathcal{T}(\mathcal{F} \cup \{\Omega, x\})$ that contain at most one occurrence of x and T_x be the subset of T_x of terms that do not contain any Ω . If ρ is a run of \mathcal{A} on $t \in T_{\Omega, x}$, we show that

$\rho(\Lambda) = [S; S']$ implies that, if there is a $t' \in T_x$ such that $t[x]_p \downarrow_{R_\Omega}$ is incompatible with all u such that $q_u \in S'$, then $t[x]_p \xrightarrow[\mathcal{R}_\Omega]{*} v$ where $v \in \mathcal{T}_\Omega$.

As a particular case, when $S' = \emptyset$, we will have the desired result.

We show the property by induction on the size of t . If $t = \Omega$, then $t \xrightarrow[\mathcal{A}]{*} [\{q_\Omega\}; \{q_x\}]$ and $t[x]_\Lambda \downarrow_{R_\Omega} = x$ is compatible with x and $q_x \in S'$.

Assume $t \xrightarrow[\mathcal{A}]{*} f([S_1; S'_1], \dots, [S_n; S'_n]) \xrightarrow[\mathcal{A}]{*} [S; S']$. Assume moreover that $t[x]_p \downarrow_{R_\Omega}$ is incompatible with any u such that $q_u \in S'$. Finally, assume w.l.o.g that for all indices $i \neq 1$, $t[x]_{p|_i} \in \mathcal{T}_\Omega$ (in other words, the first symbol of p is assumed to be 1). If $t[x]_{p|_1} \downarrow_{R_\Omega} \in \mathcal{T}_\Omega$ or if it is incompatible with any u_1 such that $q_{u_1} \in S'_1$, then by induction hypothesis, $t[x]_{p|_1} \xrightarrow[\mathcal{R}_\Omega]{*} v_1 \in \mathcal{T}_\Omega$, hence $t[x]_p \xrightarrow[\mathcal{R}_\Omega]{*} v \in \mathcal{T}_\Omega$. Otherwise, there is a term $t'_1 \in T_x$ s.t. $t[x]_{p|_1} \downarrow_{R_\Omega} \subseteq t'_1$ and t'_1 is an instance of $q_{u_1} \in S'_1$. By contradiction, suppose that $(u_1, 1) \in E$ and let $q_v = \phi(u_1, 1)$. Then $f(q_{u_1}, q_{t_2}, \dots, q_{t_n}) \xrightarrow[\mathcal{A}_{R_\Omega}]{*} q_v$ for some t_i s.t. $t|_i \xrightarrow[\mathcal{A}_{R_\Omega}]{*} q_{t_i}$. Now, we have, for every $i \geq 2$, $t|_i \downarrow_{R_\Omega} \subseteq t|_i$, if $t_i \neq \Omega$ then $t|_i$ is compatible with t_i and t_i is

compatible with $v|_i$ (actually t_i is either Ω or an instance of $v|_i$). Hence, for every $i \geq 2$, $t|_i \downarrow_{R_\Omega}$ is compatible with $v|_i$. On the other hand, $t[x]_p|_1 \downarrow_{R_\Omega}$ is compatible with u_1 , hence with $v|_1$ (u_1 is an instance of $v|_1$). It follows that $t[x]_p \downarrow_{R_\Omega}$ is either Ω or

$$f(t[x]_p|_1 \downarrow_{R_\Omega}, t|_2 \downarrow_{R_\Omega}, \dots, t_n \downarrow_{R_\Omega})$$

and in both cases it is compatible with v . Hence a contradiction.

If $t \in \mathcal{T}_\Omega$ has no index, then it is accepted by \mathcal{A} . We prove, by induction on the size of t that there is a pair $[S; S']$ such that $t \xrightarrow{\mathcal{A}}^* [S; S']$ and $q \in S$ iff $t \xrightarrow{A_{R_\Omega}}^* q$ and $q_u \in S'$ iff u is a maximal term (w.r.t. \sqsubseteq) s.t. there is a position p of Ω in t s.t. $t[x]_p \downarrow_{R_\Omega} \notin \mathcal{T}_\Omega$ and $t[x]_p \downarrow_{R_\Omega}$ is compatible with u . This will of course imply the desired property.

If $t = \Omega$, then $t \xrightarrow{\mathcal{A}} [\{q_\Omega\}; \{q_x\}]$ and $t[x]_\Lambda \downarrow_{R_\Omega} \notin \mathcal{T}_\Omega$ and $t[x]_\Lambda \downarrow_{R_\Omega} = x$ is compatible with x .

Now let $t = f(t_1, \dots, t_n)$ and $t_i \xrightarrow{\mathcal{A}}^* [S_i; S'_i]$ following the induction hypothesis. Let S' be the set of q_u s.t. u is a maximal term (w.r.t. \sqsubseteq) s.t. there is a position p of Ω in t s.t. $t[x]_p \downarrow_{R_\Omega} \notin \mathcal{T}_\Omega$ and $t[x]_p \downarrow_{R_\Omega}$ is compatible with u . Similarly, let S be as in the induction conclusion. We only have to show that $f([S_1; S'_1], \dots, [S_n; S'_n]) \xrightarrow{\mathcal{A}} [S; S']$. Let p be a position of Ω in t such that $t[x]_p \downarrow_{R_\Omega} \notin \mathcal{T}_\Omega$. (If there is no such position, then $S' = \emptyset$ and the property holds true). Assume w.l.o.g. that $p = 1 \cdot p'$. Then $t[x]_p|_1 \downarrow_{R_\Omega} \notin \mathcal{T}_\Omega$ and $t[x]_p \downarrow_{R_\Omega} = f(t[x]_p|_1 \downarrow_{R_\Omega}, t|_2 \downarrow_{R_\Omega}, \dots, t|_n \downarrow_{R_\Omega})$ is compatible with u . By maximality of u_1 , it must be an instance of $u|_1$. For $i \geq 2$, let $t|_i \downarrow_{R_\Omega}$ be accepted in state q_{t_i} . Then letting $\phi(u_1, 1)$ be q_u , we have indeed $f(q_{u_1}, q_{t_2}, \dots, q_{t_n}) \xrightarrow{A_{R_\Omega}} q_u$.

□

Example 4 Assume that the left hand sides of R are $\{f(x, g(a)), f(a, a), h(a, x), h(f(b, y), a)\}$ and let us show a run of the automaton \mathcal{A}_{noind} on $h(f(\Omega, g(\Omega)), \Omega)$:

$$\begin{aligned} \Omega &\rightarrow [q_\Omega; q_x] \\ g([q_\Omega; q_x]) &\rightarrow [q_g(a); q_x] \\ f([q_\Omega; q_x], [q_g(a); q_x]) &\rightarrow [q_\Omega; q_{f(b, y)}] \\ h([q_\Omega; q_{f(b, y)}], [q_\Omega; q_x]) &\rightarrow [q_\Omega; \emptyset] \end{aligned}$$

Example 5 If the set of left hand sides of R is $\{h(f(x, a), a), h(f(a, x), a)\}$, a run of \mathcal{A}_{noind} on $h(f(\Omega, \Omega), \Omega)$ will be given by:

$$\begin{aligned} \Omega &\rightarrow [q_\Omega; q_x] \\ f([q_\Omega; q_x], [q_\Omega; q_x]) &\rightarrow [q_{f(a, x)} \vee q_{f(x, a)}; q_{f(a, x)} \wedge q_{f(x, a)}] \\ h([q_{f(a, x)} \vee q_{f(x, a)}; q_{f(a, x)} \wedge q_{f(x, a)}], [q_\Omega; q_x]) &\rightarrow [q_\Omega; \emptyset] \end{aligned}$$

5.3 Complexity issues

As a consequence of lemma 5.23, we get a complexity result:

Theorem 5.24 *Strong sequentiality is in EXPTIME when R is left linear (possibly overlapping).*

Proof

R is strongly sequential iff the set of terms that do not have an index is contained in the set of reducible terms. Or, equivalently, R is strongly sequential if there is no term in \mathcal{T}_Ω which is accepted by both \mathcal{A}_{noind} and $\mathcal{A}_{NF(R)}$. Both automata can be computed in exponential time thanks to lemmas 5.23 and 4.15. Intersection can be done in quadratic time and the emptiness decision is again polynomial. \square

The complex construction of lemma 5.23 can only be avoided when any two strict subterm of left hand sides are comparable w.r.t. \sqsubseteq whenever they are headed with the same function symbol. In such a situation, \mathcal{A}_{R_Ω} can be made deterministic without adding any state (this is quite straightforward) and \mathcal{A}_{noind} can be computed in polynomial time. We have also seen that, in such a case, the automaton $\mathcal{A}_{NF(R)}$ can be computed in polynomial time, hence:

Corollary 5.25 *For rewrite systems R such that any two strict subterms of a left hand side of a rule which have the same top symbol are comparable w.r.t. \sqsubseteq , strong sequentiality is decidable in polynomial time.*

Note that R can be overlapping here.

Example 6

$$R = \left\{ \begin{array}{ll} f(f(x, y), z) & \rightarrow f(x, f(y, z)) \\ f(0, x) & \rightarrow 0 \\ f(s(x), y) & \rightarrow s(f(x, y)) \\ f(x, y) & \rightarrow f(y, x) \end{array} \right.$$

R satisfies the condition of corollary 5.25: any two strict subterms of the left hand sides which are headed with f (actually there is only one such term here) are comparable w.r.t. \sqsubseteq .

On the other hand, there are orthogonal rewrite systems that do not satisfy the conditions of corollary 5.25.

Example 7

$$R = \left\{ \begin{array}{ll} g(f(a, x)) & \rightarrow g(a) \\ h(f(x, a)) & \rightarrow h(a) \end{array} \right.$$

R is non-overlapping and linear. However, the two strict subterms of left hand sides: $f(a, x)$ and $f(x, a)$ are not comparable w.r.t. \sqsubseteq .

In the case of non-left linear rewrite systems, the construction does not work, even if we use automata with constraints [2, 3] instead of bottom-up tree automata. For example, consider the rewrite system with only one rule whose left side is $f(x, x)$. Then

$$f(f(g^k(f(a, a)), b), f(g^k(b), b)) \xrightarrow{R_\Omega} f(f(g^k(\Omega), b), f(g^k(b), b)) \xrightarrow{R_\Omega} \Omega$$

However, the replacement for Ω in $f(g^k(\Omega), b)$ is known only when we reach the root of the term, i.e. arbitrary “far” from the first reduction. It is not possible to keep such an information in the finite memory of an automaton with constraints.

5.4 Construction of \mathcal{A}_{ind}

Now, instead of constructing \mathcal{A}_{noind} , let us construct directly \mathcal{A}_{ind} . This will show how to find indexes in a term. First, we assume a new constant \bullet in the alphabet. Then, we start from a deterministic (completely specified) version of \mathcal{A}_{R_Ω} and complete it as follows. Each state q of \mathcal{A}_{R_Ω} is duplicated: we add the state q^\bullet which will intuitively mean that we found an index below. Then we add the following rules:

- $\Omega \rightarrow q^\bullet$ (this is a guess of an index position; we will express that it has to be applied once in each successful run)
- For each rule $f(q_1, \dots, q_i, \dots, q_n) \rightarrow q$ with $q \neq q_\Omega$, we add the rules $f(q_1, \dots, q_i^\bullet, \dots, q_n) \rightarrow q^\bullet$

Final states are those which are marked with a \bullet .

Example 8 Consider a rewrite system whose left hand sides are $f(a, x), f(f(x, y), a)$ (with 3 function symbols, f, a, b).

The states of \mathcal{A}_{ind} are $\{q_a, q_{f(x,y)}, q_\Omega, q_\bullet, q_{f(x,y)}^\bullet, q_\bullet^\bullet\}$ (states q_a^\bullet and q_b^\bullet have been removed since they are useless). The rules are:

$$\begin{array}{lll}
 \Omega \rightarrow q^\bullet & f(q_\bullet, q_\bullet) \rightarrow q_{f(x,y)} & f(q_1, q_\bullet) \rightarrow q_{f(x,y)}^\bullet \\
 \Omega \rightarrow q_\Omega & f(q_{f(x,y)}, q_{f(x,y)}) \rightarrow q_{f(x,y)} & f(q_{f(x,y)}^\bullet, q_1) \rightarrow q_{f(x,y)}^\bullet \\
 a \rightarrow q_a & f(q_\bullet, q_{f(x,y)}) \rightarrow q_{f(x,y)} & f(q_1, q_{f(x,y)}^\bullet) \rightarrow q_{f(x,y)}^\bullet \\
 b \rightarrow q_\bullet & f(q_\bullet, q_a) \rightarrow q_{f(x,y)} & f(q_\bullet^\bullet, q_2) \rightarrow q_{f(x,y)}^\bullet \\
 f(q_{f(x,y)}, q_a) \rightarrow q_\Omega & f(q_\bullet, q_\Omega) \rightarrow q_{f(x,y)} & f(q_a, q_3) \rightarrow q_\Omega \\
 f(q_{f(x,y)}^\bullet, q_a) \rightarrow q_\Omega & f(q_{f(x,y)}, q_\bullet) \rightarrow q_{f(x,y)} & f(q_\Omega, q_3) \rightarrow q_\Omega
 \end{array}$$

where q_1 is any state in $\{q_\bullet, q_{f(x,y)}\}$, q_2 is any state in $\{q_\bullet, q_{f(x,y)}, q_a, q_\Omega\}$ and q_3 is any state in $\{q_a, q_\Omega, q_\bullet, q_{f(x,y)}, q_\bullet^\bullet, q_{f(x,y)}^\bullet\}$. The final states are q_\bullet^\bullet and $q_{f(x,y)}^\bullet$.

For example, $f(\Omega, \Omega)$ is accepted since $f(q_\bullet^\bullet, q_\Omega) \rightarrow q_{f(x,y)}^\bullet$. But $f(f(\Omega, \Omega), \Omega)$ is not accepted. Moreover, this term being irreducible, the system is not strongly sequential.

Lemma 5.26 *The automaton \mathcal{A}_{ind} accepts all terms in \mathcal{T}_Ω that have an index.*

Now, if we come back to the problem of finding an index in a term, we can use \mathcal{A}_{ind} : all successful runs on t contain a \bullet -marked path from the root to an index. Consider for example the term $f(f(\Omega, \Omega), f(\Omega, \Omega))$, the only successful run is $q_{f(x,y)}^\bullet(q_{f(x,y)}^\bullet(q_\bullet^\bullet, q_\Omega), q_{f(x,y)}(q_\Omega, q_\Omega))$, which shows the path 11, which is the only index.

There is still some work to do w.r.t. reduction strategies. Indeed, so far, we have to apply the automaton on the whole term after each reduction step. Huet and Lévy, on the other hand, give a deterministic algorithm which never visits twice a node in the input term. To do something similar, we would have first to consider our automaton top-down (instead of bottom-up as we did through all the paper). Such an automaton is in general non-deterministic (and cannot be determinized). In order to avoid backtracking on the input term we would have to keep a stack of choice points and derive simultaneously the possible runs on the branch which is explored. This requires some additional implementation machinery, which is out of the scope of this paper.

6 Further applications

We believe that the tree automata approach can be used successfully to other works on reduction strategies. For example the *strong root stability* of [11] is also expressible in WSkS for left linear rewrite systems. The use of automata should also be investigated in parallel reduction strategies, such as in [19]: a run of the automaton not only gives an index position, but all index positions.
